The skin serves as a physical barrier and an immunological interface that protects the body from the external environment[1–3]. Aberrant activation of immune cells can induce common skin autoimmune diseases such as vitiligo, which are often characterized by bilateral symmetric lesions in certain anatomic regions of the body[4–6]. Understanding what orchestrates the activities of cutaneous immune cells at an organ level is necessary for the treatment of autoimmune diseases. Here we identify subsets of dermal fibroblasts that are responsible for driving patterned autoimmune activity, by using a robust mouse model of vitiligo that is based on the activation of endogenous auto-reactive CD8⁺ T cells that target epidermal melanocytes. Using a combination of single-cell analysis of skin samples from patients with vitiligo, cell-type-specific genetic knockouts and engraftment experiments, we find that among multiple interferon-γ (IFNγ)-responsive cell types in vitiligo-affected skin, dermal fibroblasts are uniquely required to recruit and activate CD8⁺ cytotoxic T cells through secreted chemokines. Anatomically distinct human dermal fibroblasts exhibit intrinsic differences in the expression of chemokines in response to IFNγ. In mouse models of vitiligo, regional IFNγ-resistant fibroblasts determine the autoimmune pattern of depigmentation in the skin. Our study identifies anatomically distinct fibroblasts with permissive or repressive IFNγ responses as the key determinant of body-level patterns of lesions in vitiligo, and highlights mesenchymal subpopulations as therapeutic targets for treating autoimmune diseases.

Vitiligo is an acquired polygenetic autoimmune disease[9]. Its defining feature is skin depigmentation, in which affected skin is unable to spontaneously recover owing to the activity of auto-reactive CD8⁺ T cells, which causes a loss of epidermal melanocytes[7,8,10–15]. Vitiligo affects 0.5% to 2% of the population worldwide[16–18]. More than 80% of patients with vitiligo have bilateral symmetric patterns of depigmentation across the central body axis, which is classified as non-segmental vitiligo[4–6]. Previous studies using a mouse model of vitiligo have shown that IFNγ is important for T cell-induced depigmentation in skin[19–21]. Although various studies have proposed underlying mechanisms[22–27], the identity of IFNγ-responsive cells that mediate this function is largely unknown. Hypotheses about the reason behind the bilateral symmetric patterns that are observed in vitiligo pathology include regional variations in microbiota distribution; the pattern of antigen expression in melanocytes; and different distributions of neuropeptides released by nerve endings[28–32]. Despite these studies, the cellular and molecular mechanisms that orchestrate the patterned activities of immune cells in the skin of patients with vitiligo remain elusive.

### Cellular IFNγ responses in vitiligo-affected skin

To understand the cellular and molecular mechanisms that lead to patterned autoimmune activity in vitiligo-affected skin (Fig. 1a, Extended Data Fig. 1a), we first analysed skin biopsies from patients with vitiligo. Immunofluorescent staining showed that melanocytes were absent within the lesion but evenly distributed in the basal epidermis of the perilesion region (Fig. 1b). Notably, the majority of the infiltrated CD8⁺ T cells were concentrated at the junction area between the lesion and the perilesion skin, which implied a local recruitment mechanism for CD8⁺ T cells.

Next we used single-cell RNA sequencing (scRNA-seq) to analyse all cell types present in patient skin (Extended Data Fig. 1b, c). Unsupervised clustering of more than 50,000 cells from 10 patients with vitiligo and 5 healthy donors yielded 8 main cell types defined by signature genes (Extended Data Fig. 1d–h, Supplementary Table 1). Further analysis of melanocytes revealed two distinct sub-clusters

# Psoriatic Fibroblasts Induce Hyperproliferation of Normal Keratinocytes in a Skin Equivalent Model in Vitro

Abstract. *A skin equivalent model has been used to fabricate tissues with psoriatic and normal cells. Psoriatic fibroblasts can induce hyperproliferative activity in normal keratinocytes. The psoriatic epidermis from lesions continues to proliferate at high rates for at least 15 days in this model, and normal fibroblasts are unable to suppress this hyperproliferation. The primary defect in psoriatic skin may reside in the dermal fibroblast.*

Decades of work have elucidated cytokine signalling and transcriptional pathways that control T cell differentiation and have led the way to targeted biologic therapies that are effective in a range of autoimmune, allergic and inflammatory diseases. Recent evidence indicates that obesity and metabolic disease can also influence the immune system[1–7], although the mechanisms and effects on immunotherapy outcomes remain largely unknown. Here, using two models of atopic dermatitis, we show that lean and obese mice mount markedly different immune responses. Obesity converted the classical type 2 T helper ($T_H2$)-predominant disease associated with atopic dermatitis to a more severe disease with prominent $T_H17$ inflammation. We also observed divergent responses to biologic therapies targeting $T_H2$ cytokines, which robustly protected lean mice but exacerbated disease in obese mice. Single-cell RNA sequencing coupled with genome-wide binding analyses revealed decreased activity of nuclear receptor peroxisome proliferator-activated receptor-γ (PPARγ) in $T_H2$ cells from obese mice relative to lean mice. Conditional ablation of PPARγ in T cells revealed that PPARγ is required to focus the in vivo $T_H$ response towards a $T_H2$-predominant state and prevent aberrant non-$T_H2$ inflammation. Treatment of obese mice with a small-molecule PPARγ agonist limited development of $T_H17$ pathology and unlocked therapeutic responsiveness to targeted anti-$T_H2$ biologic therapies. These studies reveal the effects of obesity on immunological disease and suggest a precision medicine approach to target the immune dysregulation caused by obesity.

Emerging clinical data of multiple immunological diseases including atopy and asthma indicate that obese patients have more severe disease and exhibit resistance to therapies that are effective in lean patients[8–13], although the mechanisms underlying these observations remain unclear. To gain mechanistic insights into the immunopathological effects of obesity, we employed a well-characterized mouse model of atopic dermatitis[14,15] (AD). We challenged obese mice fed high-fat diet (HFD) and lean controls with the vitamin $D_3$ analogue MC903 to induce AD on the ear (Fig. 1a). The obese mice displayed a markedly increased inflammatory response, evidenced by an approximately twofold to fourfold increase in ear thickness relative to lean mice that received the same MC903 treatment (Fig. 1b). The MC903-treated ears of the obese mice had more severe erythema and scale, hallmarks of dermal inflammation (Fig. 1c). Histological evaluation demonstrated greater expansions of the epidermal and dermal layers in obese mice, along with a marked increase in leukocytic infiltration (Fig. 1d, dashed line). Of note, studies modulating duration of the HFD (Extended Data Fig. 1a–d) and using monogenic models of obesity on normal or HFD (Extended data Fig. 1e–j) suggested that the increased ear thickness and inflammation seen in obesity was at least partially dependent on HFD. Further, we observed a persistent inflammatory effect of obesity, even after weight loss (Extended Data Fig. 1k–m). Additionally, obesity increased disease severity, including after weight loss, in a second model of AD (Extended Data Fig. 2a–g), involving sensitization to ovalbumin (OVA) followed by serial tape-stripping and exposure to a mixture of OVA and papain (TOP). Finally, this increased inflammatory response was not limited to atopic diseases of the skin, as challenging lean and obese mice in an experimental model of allergic airway disease (ovalbumin sensitization and challenge) yielded increased cellular infiltration across multiple immune subsets in the bronchial–alveolar lavage fluid of obese mice and increased $CD4^+$ and $CD8^+$ T cells in the draining lymph node of obese mice (Extended Data Fig. 2h–j). Together, these results show that obesity exacerbates multiple mouse models of atopic disease.

**Direction technique digitale :** Laurent Elgard

# Étude prospective exploratoire en vie réelle non interventionnelle

- **Objectif principal :**

- Mesurer l'observance déclarée par le patient au cours du temps à 3, 6 et 9 mois après initiation ou modification d'un traitement pour son psoriasis.

- **Critère de jugement principal :**

- L'observance sera évaluée par le **score de Girerd** à 3, 6 et 9 mois renseigné par les patients, automatiquement sollicités par email ou SMS

- **Objectifs secondaires :**

- Évaluer l'adhésion thérapeutique du patient à l'issue de la première consultation par l'utilisation du questionnaire **de satisfaction d'adhésion thérapeutique (AdT)**.

- Rechercher des associations entre des facteurs cliniques (liés à la maladie, aux traitements et aux comorbidités) et socio-démographiques, et une bonne observance au traitement du psoriasis.

- Rechercher des associations entre des facteurs cliniques et socio-démographiques , et une bonne adhésion au traitement du psoriasis.

# Matériel et méthodes

- Inclusion **consécutivement** pendant 3 mois **tous** les patients atteints de psoriasis consultant pour **débuter ou modifier** un traitement
- Les investigateurs n'auront pas connaissance des données d'observance et d'adhésion renseignées par les patients en dehors de leur consultation.
- Après remise de la fiche d'information et recueil et signature du consentement pour participer à l'étude, le **questionnaire d'adhésion** AdT (inclusion) est adressé dans les 48 heures par voie électronique ou SMS à chaque patient selon le choix de celui-ci et un **questionnaire d'observance de Girerd** est rempli par chaque patient à 3, 6 et 9 mois.
- Au niveau statistique il est prévu d'inclure un nombre minimal de **650 patients** et les analyses seront réalisées avec le logiciel STATA (versions 13).
- La société ClinInfo a été sélectionnée pour la réalisation de la plateforme numérique qui met à disposition les questionnaires en ligne, et permet de notifier aux patients le moment où ils sont invités à y répondre (email, sms).

# Conclusion

- Financée par soutien institutionnel et Appel d’offre libéral de la SFD
- Nécessité de 650 inclusions
- Besoin d’une forte participation
